(Dated: October 3, 2023)

The aim of this report is to see how different regression method affects the data it is applied to. More concretely, we will look at the three different methods ordinary least squares (OLS), Ridge and LASSO. We will also apply bias variance trade of as well as cross validation on the data sets used to evaluate our models. What we found was that ... regression with parameter ... best fitted the topological data analysis...

This report, crafted by Mia Synnøve Frivik, Andrea Myrvang, Max Jan Willem Schuringa, and Janita Ovidie Sandtrøen Willumsen, aims to explore the effects of different regression methods on data modeling, focusing on Ordinary Least Squares (OLS), Ridge, and LASSO. Utilizing synthetic data from the Franke function. Our analysis puts a lens on how these regression methods handle various data types. Our goal is to ascertain how each method influences predictive modeling, particularly in identifying high-risk zones for events like avalanches and floods. We'll employ bias-variance trade-off analysis and cross-validation to rigorously evaluate our models' performances and ensure their reliability. Findings indicate that...

## I. INTRODUCTION

Machine learning is a powerfull tool usfull in many fields of reasarche. One illustration of its utility is its application to terrain data analysis. Through the creation of terrain models from real data of a specific geographic area, one can effectively anticipate high-risk avalanche zones[2], potentially leading to life-saving interventions. This methods can extends to addressing concerns related to floods, which has become a hot topic this past month following the storm Hans. It can also help in aiding with spatial planning challenges. which is usefull in big citys all over the world. It is fair to say machine learning possesses immense potential to contribute to the solutions of complex and relevant challenges in our modern society, encompassing climate-related issues, urban planning, and life-saving endeavors.

In this report er are going to study three different regres- sion methods, ordinary least squares (OLS), Ridge and LASSO and see how these method compare to eachother when applied to different data sets. First we are going to use the Franke function to make dummy data to val- idate if our models works. When plotted in the interval  $[0, 1]$  this function looks like a mountain and a valley, which is a perfect starting point when we later want to apply these methods on real digital terrain data taken from <https://earthexplorer.usgs.gov/>. To more ac- curatly simulate the realism of practical machine learn- ing scenarios, we will impose limitations on our datasets. Additionally, we will employ techniques such as boot- strapping and cross-validation to expand our dataset size and assess their impact on model validation.

## II. THEORY

### A. Linear regression methods

Linear regression is a foundational statistical modeling technique employed for the prediction of continuous tar- get variables based on one or more input features. It operates under the assumption that there exists a linear relationship between the input features and the target variable, which is mathematically expressed as:

$$\hat{y} = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_p x_p$$

In this equation,  $\hat{y}$  denotes the predicted target vari- able, while  $x_1, x_2, \dots, x_p$  represent the input features. The coefficients  $\beta_0, \beta_1, \beta_2, \dots, \beta_p$  are parameters that correspond to each respective feature. The primary ob- jective of linear regression is to determine these coeffi- cients to establish the optimal linear model that best fits the given data.

Linear regression encompasses several variants, each offering unique characteristics and advantages. In this particular context, we will narrow our focus to three fundamental techniques, Ordinary Least Squares (OLS), Ridge regression, and Lasso regression. These techniques will be employed in the context of analyzing the two- dimensional Franke function.

#### 1. Ordinary least squares (OLS)

Ordinary Least Squares (OLS) stands as a fundamental technique in regression analysis, where the aim is to cre- ate a model that minimize the diffrence from the observed data and the predicted model.

A linear regression model has the following form :

$$f(\mathbf{X}) = \beta_0 + \sum_{i=1}^p X_i \beta_i [1] \quad (1)$$

Where  $\beta$  is the coefficients and  $\mathbf{X}$  the design matrix. It is important to note that this method assumes that either the function is linear or approximately linear.

## 2. Ordinary least squares (OLS)

Ordinary Least Squares (OLS) stands as a fundamental technique in regression analysis, with the primary objective of creating a model that minimizes the discrepancy between observed data and the predicted model. This is achieved by estimating the coefficients in a linear regression model, as defined in Equation (1), while minimizing the Mean Squared Error (MSE). To minimize the MSE, we calculate the optimal  $\beta$  values. This involves taking the derivative of the cost function, as shown in Equation (2), and setting it to zero.

$$C(\beta) = \frac{1}{n} \{(\mathbf{y} - \mathbf{X}\beta)^T(\mathbf{y} - \mathbf{X}\beta)\} \quad (2)$$

By solving  $\frac{\partial C(\beta)}{\partial \beta} = 0$ , we determine that for OLS, the optimal  $\beta$  values can be obtained by solving Equation (3).

$$\beta = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y} \quad (3)$$

Additionally, OLS possesses other properties that are relevant to this project, such as the expectation value and variance. These properties come into play when applying the bias-variance trade-off to evaluate our models, and they can be expressed as follows:

$$\mathbb{E}_{OLS}(y_i) = \mathbf{X}i, * \beta \quad (4)$$

$$\mathbb{E}_{OLS}(\beta) = \beta \quad (5)$$

$$\mathbb{V}_{OLS}(y_i) = \sigma^2 \quad (6)$$

$$\mathbb{V}_{OLS}(\hat{\beta}) = \sigma^2 (\mathbf{X}^T \mathbf{X})^{-1} \quad (7)$$

For a comprehensive step-by-step derivation of these expressions, please refer to Appendix A. OLS, as a regression method, relies on specific assumptions about the data it is applied to. If these assumptions are not met by the dataset, the model's accuracy may be compromised.

## Write about positiv and negativ things about OLS

While OLS is a straightforward and efficient linear regression method to implement, its limitations become particularly evident when dealing with datasets that contain

substantial amounts of noise. In response to the limitations of OLS in noisy datasets, two other linear regression methods have been developed namely Ridge and LASSO regression.

## 3. Ridge

Ridge regression closely resembles OLS, but it has the addition of a term in the cost function, as depicted in the equation (8).

$$C(X, \beta) = \{(\mathbf{y} - \mathbf{X}\beta)^T(\mathbf{y} - \mathbf{X}\beta)\} + \lambda \beta^T \beta \quad (8)$$

If we take the derivative of the cost function  $\frac{\partial C(X, \beta)}{\partial \beta}$  and solve the equation when the derivative is zero, we then obtain the equation for the optimal  $\beta$ :

$$\beta = (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y} \quad (9)$$

This extra term  $\lambda \mathbf{I}$  helps controlling the size of the coefficients, if  $\lambda$  is small, then ..

For the Bias variance trade off we will also need the following properties:

$$\mathbb{E}(\beta_{Ridge}) = (X^T X + \lambda I)^{-1} (X^T X) \beta \quad (10)$$

$$\mathbb{V}(\beta_{Ridge}) = \sigma^2 [X^T X + \lambda I]^{-1} X^T X \{[X^T X + \lambda I]^{-1}\}^T \quad (11)$$

Calculations for both the optimal  $\beta$  and variance can be found in the appendix

## 4. LASSO

### B. MSE

### C. Resampling techniques

The main restriction in machine learning is the amount of data points available to create the model out of. It may be the case where one has done a costly and time-consuming experiment and is left with a small number of data. It is therefore extremely useful to have methods where one can reuse the data multiple times thereby creating a relatively large dataset from the small number of datapoints. In this report we are going to use two different methods, the first is called bootstrap and the second one is cross validation.

### 1. Bootstrap

The bootstrap method is a resampling procedure that uses data from one sample to generate a sampling distribution by repeatedly taking random samples from the known sample, with replacement. This means that if we

have a data set  $D$  with  $n$  data points. The elements in this data set can be representatet in the following way:

$$D = d_1, d_2, d_3, d_4, \dots, d_n \quad (12)$$

Then by aplying the bootstarp method on this data set one possible output  $D^*$  can be:

$$D^* = d_3, d_n, d_4, d_4, \dots, d_2 \quad (13)$$

From this example we see that one observation can appear multiple times in the new dataset. We can take this method a step further and create "new" data points by extracting multible data points from the dataset and take the mean of all thise values:

$$d_{new} = \frac{1}{k}(d_1, \dots d_k) \quad (14)$$

This gives us a method of producing lots of "new" dataset from limited data points to train our model with. For each of this data-sets the mean and standard deviation can be calculated to evaluate the model statistically.

One huge advatage of using the boostrap method is that the data can be split in to test and train before shuffling the data, this means that the test data can bee kept entirely separate from the creation of the model. When we den test the model it will be on a dataset that has nothing to do with crating the model and will therefore show how god the model represent real data. **Write something about large numbers law, also disadvantages and advantage**

## 2. Cross validation

Cross validation (CV), specifically  $k$ -fold cross validation, is a technique designed to assess how well a model will generalize to an independent dataset. Unlike the bootstrap method, which samples with replacement, CV partitions the original dataset into  $k$  distinct subsets or "folds". One of these folds is kept as the test set, while the remaining  $k - 1$  folds are used for training the model. This process is repeated  $k$  times, each time with a different fold reserved as the test set and the remaining folds as the training set. Given a dataset  $D$  with  $n$  data points represented as:

$$D = \{d_1, d_2, d_3, \dots, d_n\} \quad (15)$$

For  $k = 5$ , an example partition might be:

$$\text{Fold 1} = \{d_1, d_2, \dots, d_{\frac{n}{5}}\} \quad (16)$$

$$\text{Fold 2} = \{d_{\frac{n}{5}+1}, d_{\frac{n}{5}+2}, \dots, d_{2 \times \frac{n}{5}}\} \quad (17)$$

$$\vdots \quad (18)$$

$$\text{Fold 5} = \{d_{4 \times \frac{n}{5}+1}, d_{4 \times \frac{n}{5}+2}, \dots, d_n\} \quad (19)$$

In each iteration, one of these folds is reserved for testing and the others for training, cycling through until each

fold has been the test set once. The model's performance is then averaged over the  $k$  test sets to produce a single estimation. The advantage of CV is its ability to utilize the entire dataset for both training and testing, which can be very helpfull when data is limited. By averaging over multiple trials, CV reduces the variance associated with a single random train-test split, providing a more robust measure of model performance. However, CV can be computationally intensive, especially for large  $k$  values or large datasets. Also, unlike the bootstrap method where test data is entirely separate from training, there's an overlap in the training data across folds in CV. This means that CV may sometimes be overly optimistic about a model's performance. In the context of our study, CV aids in parameter tuning, especially for models like Ridge and LASSO where the regularization strength is crucial.

## D. Bias-variance trade-off

The Bias-varinace trade-off is a measuerment on how accurately a model fit the real data.

## III. METHOD

In the first part of this project a function called Franke function was used as the data analysed. The Franke function is given by the following equation:

$$\begin{aligned} f(x, y) = & \frac{3}{4} \exp \left( -\frac{(9x-2)^2}{4} - \frac{(9y-2)^2}{4} \right) \\ & + \frac{3}{4} \exp \left( -\frac{(9x+1)^2}{49} - \frac{(9y+1)^2}{10} \right) \\ & + \frac{1}{2} \exp \left( -\frac{(9x-7)^2}{4} - \frac{(9y-3)^2}{4} \right) \\ & - \frac{1}{5} \exp \left( -(9x-4)^2 - (9y-7)^2 \right) \end{aligned}$$

Figure 1. A plot of the Franke function

This function was fitted with the OLS method, and polynomials with varying degrees was used to create the design matrix. Since the design matrix in this case was non-invertible, singular value decomposition was used to create the  $\beta$ -values needed to create a model of the dataset. The mean square error and the R2 score was calculated for both the testing and training datasets. The result of this analyses is shown if figures (2), (3) and ... Lastly a plott of the coefficients were made for each polynomial degree...

Next Ridge and LASSO regression was used on the Franke function, to see if these methods have a better fit than what was obtained with OLS. Different values for  $\lambda$  was used to obtain the best fit as possible for each polynomial degree. For Ridge equation (9) was used to calculate the coefficients and for LASSO ....

### A. Cross Validation Methodology

In the pursuit of assessing the robustness and reliability of Ridge regression models, we employed cross-validation, specifically scrutinizing the impact of varying regularization parameters, denoted as  $\lambda$ . The function `k_fold`, was developed to execute the k-fold cross-validation technique, accepting the dataset and an integer  $k$  as arguments, and subsequently partitioning the data into  $k$  randomized subsets (folds). It returns  $k$  pairs of training and test indices, each representing a distinct division of the data, enabling model evaluation across varied data scenarios.

For each  $\lambda$  value in a logarithmically spaced array of  $\lambda$  values, denoted `lambdas`, the Ridge regression model was trained and validated  $k$  times - once per fold. Specifically, for every tuple (train\_indices, test\_indices) produced by `k_fold(data, k)`, the data was divided into training and test sets ( $x_{\text{train}}, y_{\text{train}}, x_{\text{test}}, y_{\text{test}}$ ). Subsequently, the `design_matrix` function generated polynomial feature matrices  $X_{\text{train}}$  and  $X_{\text{test}}$  from the  $x$  and  $y$  values, using a specified polynomial degree.

The Ridge model, instantiated with the current  $\lambda$ , was then fitted with  $X_{\text{train}}$  and  $y_{\text{train}}$ , and predictions  $y_{\text{pred}}$  were made using  $X_{\text{test}}$ . The Mean Squared Error (MSE) between the predictions and actual test values  $y_{\text{test}}$  was computed and stored in a scores array. The MSE values were averaged per  $\lambda$ , providing an unbiased performance metric, and facilitating the analysis and visualization of how distinct regularization parameters influenced model performance.

## IV. RESULTS

### A. Result for Franke function

Our initial step involved the application of OLS to the Franke function without noise. This analysis was conducted without employing any resampling techniques,

and our dataset consisted of 100 data points. The results for the MSE and R2 score is shown in figure (2)

Figure 2. Plot showing the MSE and R2 score for the franke function without noise. The regression method used was OLS

The next step was to include noise given by the normal distribution  $\mathcal{N}(0, 1)$ . Figure (3) shows how the MSE and R2 score changes when noise is included in to the data set.

Figure 3. Plot showing the MSE and R2 score for the franke function with noise  $\mathcal{N}(0, 1)$ . The regression method used was OLS

For Ridge  
solve the beta plot

### B. Results for terrain data

## V. DISCUSSION

From figure (2) we see that when our data set does not include noise the MSE for the training data gets lower with increases in complexity, while the R2 score gets closer and closer to 1. But when we introduce noise we see from figure (3) that for our test data the MSE actually increase with higher complexity.

The dataset containing the test data consists of 20% of the original dataset. This implies that the number of

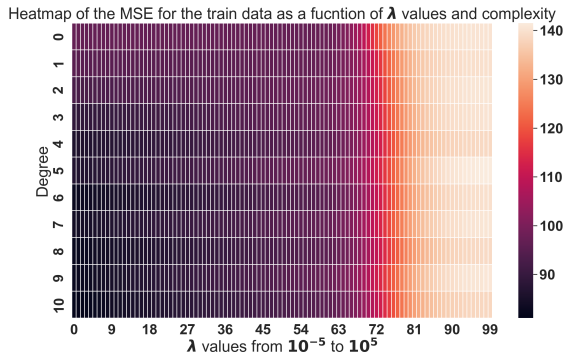

Figure 4.

Figure 5.

points in the test data is significantly smaller than that in the training data. We anticipate that by increasing the number of data points, the MSE for the model created using the test data will converge towards that of the training model.

## VI. CONCLUSION

## VII. ACKNOWLEDGEMENT

We would like to thank Morten Hjorth-Jensen for his amazing and well crafted jupyter notebooks. Additionally, we would like to acknowledge the valuable inspiration provided by ChatGPT throughout the report-writing process.

## Appendix A: Mean values and variances calculations

The main regression method used in this report is the ordinary least squares method. This appendix shows the calculations for some of the equations used to produce the results shown in this report. We have assumed that our data can be described by the continuous function  $f(\mathbf{x})$ , and an error term  $\epsilon \sim N(0, \sigma^2)$ . If we approximate the function with the solution derived from a model  $\tilde{\mathbf{y}} = \mathbf{X}\boldsymbol{\beta}$  the data can be described with  $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$ . The expectation value

$$\begin{aligned}\mathbb{E}(\mathbf{y}) &= \mathbb{E}(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}) \\ &= \mathbb{E}(\mathbf{X}\boldsymbol{\beta}) + \mathbb{E}(\boldsymbol{\epsilon}) && \text{where the expected value } \boldsymbol{\epsilon} = 0 \\ \mathbb{E}(y_i) &= \sum_{j=0}^{P-1} X_{i,j}\beta_j && \text{for the each element} \\ &= X_{i,*}\beta_i && \text{where } * \text{ replace the sum over index } i\end{aligned}$$

The variance for the element  $y_i$  can be found by

$$\begin{aligned}\mathbb{V}(y_i) &= \mathbb{E}[(y_i - \mathbb{E}(y_i))^2] \\ &= \mathbb{E}(y_i^2) - (\mathbb{E}(y_i))^2 \\ &= \mathbb{E}((X_{i,*}\beta_i + \epsilon_i)^2) - (X_{i,*}\beta_i)^2 \\ &= \mathbb{E}((X_{i,*}\beta_i)^2 + 2\epsilon_i X_{i,*}\beta_i + \epsilon_i^2) - (X_{i,*}\beta_i)^2 \\ &= \mathbb{E}((X_{i,*}\beta_i)^2) + \mathbb{E}(2\epsilon_i X_{i,*}\beta_i) + \mathbb{E}(\epsilon_i^2) - (X_{i,*}\beta_i)^2 \\ &= (X_{i,*}\beta_i)^2 + \mathbb{E}(\epsilon_i^2) - (X_{i,*}\beta_i)^2 \\ &= \mathbb{E}(\epsilon_i^2) = \sigma^2\end{aligned}$$

The expression for the optimal parameter

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$$

We find the expected value of  $\hat{\boldsymbol{\beta}}$

$$\begin{aligned}\mathbb{E}(\hat{\boldsymbol{\beta}}) &= \mathbb{E}((\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}) \\ &= (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbb{E}(\mathbf{y}) && \text{using that } \mathbf{X} \text{ is a non-stochastic variable} \\ &= (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{X}\boldsymbol{\beta} && \text{using } \mathbb{E}(\mathbf{y}) = \mathbf{X}\boldsymbol{\beta} \\ &= \boldsymbol{\beta}\end{aligned}$$

we can find the variance by

$$\begin{aligned}\mathbb{V}(\hat{\boldsymbol{\beta}}) &= \mathbb{E}[(\hat{\boldsymbol{\beta}} - \mathbb{E}(\hat{\boldsymbol{\beta}}))^2] \\ &= \mathbb{E}(\hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^T) - \mathbb{E}(\hat{\boldsymbol{\beta}})^2 \\ &= \mathbb{E}(((\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y})((\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y})^T) - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^T \\ &= \mathbb{E}((\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y} \mathbf{y}^T \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1}) - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^T \\ &= (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbb{E}(\mathbf{y} \mathbf{y}^T) \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1} - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^T \\ &= (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T (\mathbf{X}\boldsymbol{\beta}\boldsymbol{\beta}^T \mathbf{X}^T + \sigma^2 \mathbf{I}) \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1} - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^T \\ &= \boldsymbol{\beta}\boldsymbol{\beta}^T + \sigma^2((\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1}) - \hat{\boldsymbol{\beta}}\hat{\boldsymbol{\beta}}^T \\ &= \sigma^2(\mathbf{X}^T \mathbf{X})^{-1}\end{aligned}$$

Knowing the expectation value and the variance of  $\hat{\beta}$ , we can define a confidence intervall for each  $\hat{\beta}_j \pm std(\hat{\beta}_j)$  for  $j = 1, 2, \dots, P - 1$ .

The optimal  $\hat{\beta}^{Ridge}$  can be derived from MSE, and is defined as

$$\hat{\beta}^{Ridge} = (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y}$$

The expectation value is then

$$\begin{aligned} \mathbb{E}(\hat{\beta}^{Ridge}) &= \mathbb{E}((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y}) \\ &= (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbb{E}(\mathbf{y}) && \text{since } \mathbf{X} \text{ and } \lambda \mathbf{I} \text{ are non-stochastic variables} \\ &= (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{X} \boldsymbol{\beta} && \text{using } \mathbb{E}(\mathbf{y}) \text{ from exercise 1} \end{aligned}$$

For  $\lambda = 0$  we have  $\mathbb{E}(\hat{\beta}^{OLS})$ . The variance

$$\begin{aligned} \mathbb{V}(\hat{\beta}^{Ridge}) &= \mathbb{E}(\hat{\beta}_R \hat{\beta}_R^T) - (\mathbb{E}(\hat{\beta}_R))^2 \\ &= \mathbb{E}(((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y})((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y})^T) - (\mathbb{E}(\hat{\beta}_R))^2 \\ &= \mathbb{E}((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y} \mathbf{y}^T \mathbf{X} ((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1})^T) - (\mathbb{E}(\hat{\beta}_R))^2 \\ &= (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbb{E}(\mathbf{y} \mathbf{y}^T) \mathbf{X} ((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1})^T - (\mathbb{E}(\hat{\beta}_R))^2 \\ &= (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T (\mathbf{X} \boldsymbol{\beta} \boldsymbol{\beta}^T \mathbf{X}^T + \sigma^2 \mathbf{I}) \mathbf{X} ((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1})^T - (\mathbb{E}(\hat{\beta}_R))^2 \\ &= \sigma^2 (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{X} ((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1})^T + (\mathbb{E}(\hat{\beta}_R))^2 - (\mathbb{E}(\hat{\beta}_R))^2 \\ &= \sigma^2 (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{X} ((\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1})^T \end{aligned}$$

## Appendix B: Bias-variance trade-off
